Summary. Recent reports on a possible role for neutral proteinase(s), mainly serine proteinase(s), in the development of the nephrotic syndrome have prompted us to investigate the proteinase inhibitor activity of plasma $\alpha_1$-proteinase inhibitor ($\alpha_1$-PI, formerly referred to as $\alpha_1$-antitrypsin), which regulates a wide range of serine proteinases, including elastase. The concentration of plasma $\alpha_1$-PI was significantly lower in idiopathic nephrotic syndrome (INS) both during relapse and in remission than in either chance proteinuria and/or haematuria or normal controls. The anti-elastase activity, one of the serine proteinase inhibitor effects of $\alpha_1$-PI, was also decreased both during relapse and remission of INS. In contrast, the anti-trypsin activity was decreased upon relapse but normal in remission. The concentration of plasma $\alpha_1$-PI correlated with the plasma anti-elastase activity, but not with the anti-trypsin activity. The presence of decreased levels of both plasma $\alpha_1$-PI inhibitor concentration and anti-elastase activity, not only during relapse but also in remission of INS, was difficult to explain in the present study, but may be a predisposing factor for the development of proteinuria and resultant nephrotic syndrome.

INTRODUCTION

Recently, several studies have demonstrated a possible role for certain neutral proteinases, mainly serine proteinase(s), in reducing anionic sites on the glomerular basement membrane and in the development of proteinuria. In normal subjects, proteinase is inactivated by a requisite level of various proteinase inhibitors. However, in subjects with decreased plasma anti-proteinase activities, a subsequent proteolytic injury by proteinases would be difficult to control.

Of the seven major plasma proteinase inhibitors, $\alpha_1$-proteinase inhibitor ($\alpha_1$-PI) is present in the greatest quantities in the molars, and is capable of inhibiting neutral proteinases including serine proteinases. At a clinical level, plasma $\alpha_1$-PI is considered to play a role in the regulation of haemostasis as one of the thrombin inhibitors such as $\alpha_2$-macroglobulin and anti-thrombin III, and has also been viewed as one of the acute phase reactants. $\alpha_1$-PI inhibits various proteinases including serine proteinases such as pancreatic trypsin (the name is derived from this activity), elastase, cathepsin G, chymotrypsin, and thrombin. However, the anti-trypsin effect of $\alpha_1$-PI is no longer viewed as its major function, because the half-time of the association rate with trypsin is much longer than that with either elastase or cathepsin G.

Although the plasma concentration of $\alpha_1$-PI has been reported to decrease in idiopathic nephrotic syndrome (INS), the pathological and causative significances have been discussed mainly in reference to the resulting coagulation abnormality. However, on the basis of serial observations which demonstrate a possible role for neutral proteinase in initiating nephrotic syndrome, the proteinase inhibitor activity of the plasma $\alpha_1$-PI on neutral proteinases needs to be investigated in relation to the pathological state of INS. The aim of this study is to clarify both the quantitative and functional changes of plasma $\alpha_1$-PI as an anti-serine proteinase inhibitor in patients with INS.

SUBJECTS AND METHODS

Twenty-two pediatric patients with INS including 13 patients during relapse, 20 patients with chance proteinuria and/or hematuria (CPH), and 10 normal control subjects were included in this study. Clinical
characteristics of the patients are shown in Table 1.

Concentrations (mg/dl) of plasma $\alpha$-PI were determined by a single radial immunodiffusion technique. The two proteinase inhibitor activities of $\alpha$-PI were measured, as follows, by the method of Beaty with some modification.

**Anti-trypsin activity**: A 30 μl sample of plasma was diluted with 300 μl of 0.001 M Tris-HCl buffer at pH 8.0 in a test tube. 100 μl of diluted plasma was added to a test tube containing 100 μl of trypsin solution (Porcine trypsin, Sigma, 5 mg/ml in 0.01 M Tris-HCl buffer at pH 8.0) and allowed to incubate at room temperature for 3 min. To the reaction mixtures, 3.0 ml of substrate solution (0.58 mM Benzoyl L-arginine ethyl ester HCl, Sigma) was added and incubated at 25°C. The changes in optical density at 253 nm (OD$_{253}$) was read with standard trypsin solutions and ΔOD$_{253}$/min was calculated. Plasma anti-trypsin activity was expressed as units of trypsin inhibited by plasma per min (U/ml).

**Anti-elastase activity**: A sample of 5 μl of plasma was added to a test tube containing 1.1 ml of elastase solution (Porcine pancreatic elastase, Sigma, 0.3 mg in 5.0 ml of 0.2 M Tris-HCl buffer at pH 8.0) and allowed to incubate at room temperature for 3 min. To the reaction mixture, 2.0 ml of substrate solution (succinyl-L-alanyl-L-alanyl-p-nitroanilide, 45.0 mg in 20.0 ml of Tris-HCl buffer) was added and incubated at 40°C to accelerate the reaction. The changes in optical density at 410 nm were read with standard elastase solutions. Plasma anti-elastase activity was expressed as units of elastase inhibited by 1.0 ml of plasma per min (U/ml).

Statistical analysis of the mean differences was carried out using Student's t-test.

### RESULTS

1. **Concentrations of plasma $\alpha$-PI (Fig. 1)**

The protein concentrations of plasma $\alpha$-PI were 189.5±31.7 mg/dl in INS during relapse, 212.9±23.7 mg/dl in CPH, and 216.7±24.9 mg/dl in control subjects. The values in INS during relapse and remission were significantly lower than those in CPH and controls (p<0.02, p<0.01 respectively). There was no significant difference between the values of INS during both relapse and remission.

2. **Plasma anti-trypsin activity (Fig. 2)**

Plasma anti-trypsin activity of $\alpha$-PI was 321.0±156.3 U/ml in INS during relapse, 410.2±127.0 U/ml in INS in remission, 447.1±96.8 U/ml CPH, and 495.1 U/ml in controls. The mean value in INS during relapse was significantly lower than that in CPH (p<0.01) and in controls (p<0.02). No significant difference was found between the values of INS during relapse and remission.

3. **Plasma anti-elastase activity (Fig. 3)**

Anti-elastase activity of $\alpha$-PI was 1211.7±377.1 U/
The possible relation between α1-PI and renal disease was first suggested by Miller in a case report of glomerulonephritis presented with congenital α1-PI deficiency. Later, three cases of congenital α1-PI deficiency were reported to have membranoproliferative glomerulonephritis with glomerular deposition of C3, IgM, and α1-PI or without glomerular deposits. In addition, congenital nephrotic syndrome

4. Relation between the protein concentrations of plasma α1-PI and the proteinase inhibitory activities.

A correlation was found between the protein concentrations of plasma α1-PI and the anti-trypsin activity in INS both during relapse (r = 0.71, p < 0.01) and in remission (r = 0.47, p < 0.05). There was no correlation between the values in CPH and in controls. A significant correlation was found between the protein concentrations of plasma α1-PI and the anti-elastase activity in INS both during relapse (r = 0.72, p < 0.01) and in remission (r = 0.72, p < 0.01).

DISCUSSION

The possible relation between α1-PI and renal disease was first suggested by Miller in a case report of glomerulonephritis presented with congenital α1-PI deficiency. Later, three cases of congenital α1-PI deficiency were reported to have membranoproliferative glomerulonephritis with glomerular deposition of C3, IgM, and α1-PI or without glomerular deposits. In addition, congenital nephrotic syndrome

ml in INS during relapse, 1360.3 ± 372.5 U/ml in INS in remission, 1520.3 ± 160.3 U/ml in CPH, and 1,604 ± 153.2 U/ml. The mean value in INS during relapse was significantly lower than that in CPH (p < 0.02) and controls (p < 0.02).
and rapidly progressive glomerulonephritis were also reported to have developed in patients with congenital $\alpha_1$-PI deficiency, suggesting a possible role for the inhibitor in preventing renal diseases.

In this study, plasma $\alpha_1$-PI concentrations were significantly decreased in INS patients, not only during relapse but also in remission, indicating that INS patients have a lower inhibitory activity against some proteinases even in remission than normal subjects. However, since the degree of decrease in plasma $\alpha_1$-PI activity was slight, the INS patients did not show any severe clinical manifestations as observed in congenital $\alpha_1$-PI deficiency.

Although the measured inhibitory effect of plasma $\alpha_1$-PI on elastase was found to be decreased in INS both during relapse and in remission, the effect on trypsin was not decreased in remission. Several studies have demonstrated decreased plasma $\alpha_1$-PI concentrations in INS; however, the functional changes of the inhibitor have not been examined. The present study is the first to demonstrate both the decreased $\alpha_1$-PI concentrations and the decreased inhibitory activity on elastase in remission of INS.

In aminonucleoside nephrotic rats, Davin et al. has demonstrated that neutral proteinases might be involved in damage to the glomerular basement membrane (GBM) and in the subsequent development damage could be explained as follows: 1) Aminonucleoside can induce an in vivo release of proteinases from leucocytes. 2) Neutral proteinases generated by cells derived from the glomerular mesangium are capable of degrading GBM glycoproteins. 3) A metalloproteinase has also been recently detected in patients presenting with acute renal failure. A role for plasma proteinases in the degradation of GBM is therefore possible, despite the fact that their action is theoretically counteracted by the presence of strong plasma enzyme inhibitors. Davin et al. have demonstrated that urinary excretion of GBM components such as laminin and type IV collagen were increased in aminonucleoside nephrotic rats and that decreased GBM anionic sites were observed in these rats. Furthermore, a significant inhibition of neutral proteinase activity was observed with phenyl-ethylsulfonylfluoride, soybean trypsin inhibitor, and aprotinin, but not with EDTA or cysteine, which suggested that the increased enzymatic activity mainly resulted from serine proteinases in these animals.

The suggestion that the proteinases involved in the damage to the GBM might be one of the proteinases which could be inhibited by $\alpha_1$-PI supports our hypothesis that the decreased plasma concentration and proteolytic activity of the plasma $\alpha_1$-PI may be a predisposing factor to the development of INS. The molecular weight of $\alpha_1$-PI is small (53,000), and $\alpha_1$-PI is normally present in high concentrations in plasma.

In summary, we have demonstrated that the decreased plasma $\alpha_1$-PI concentrations and decreased proteolytic activity are not only present during relapse but also in remission of INS. Under normal conditions, plasma $\alpha_1$-PI may be acting as a defense against proteolytic injury of kidney tissue. In INS patients, however, lower plasma $\alpha_1$-PI concentrations may result in proteolytic damage to kidney tissue, and in nephrotic syndrome as well.
